Here are my results to date.

It seems the best fit is a log-logistic model where the exposure metric is cumulative exposure x latency.

The real problem is the data do not extend down enough to clearly see what the bottom of the curve looks like.

Also, the prevalence in the high dose groups are lower than expected based on extrapolation from the lower groups, almost as if there were a plateau.

I assume that is not real, and is just due to random variation in the data.

If we were to proceed with a log-logistic model, the POD will be very low, and will depend strongly on what we assume or specify about the "baseline" condition.
